

Process and device for contacting a wire conductor

The present invention relates to a process according to the preamble to Claim 1 and also to a device having the features of Claim 29 or 34 for implementing the process.

INS.

A1

- 5 In particular in the course of the manufacture of transponder units arranged on a substrate and comprising, by way of essential elements, a wire coil and a chip unit which has been contacted with the ends of the coil, the contacting of the ends of the coil with the terminal areas 10 of the chip unit proves to be a particular problem. This is mainly due to the very small dimensions of the components to be connected to one another. For instance, the terminal areas of a chip unit, which as a rule are of square or approximately square design, customarily have an 15 edge length of about 100 to 150 µm. By way of coil wire, particularly for the purpose of forming low-frequency coils, use is made of a copper wire having a diameter which as a rule amounts to around 50 µm.
- 20 As can be gathered from WO 91/16718, for instance, in the past a direct contacting of the ends of the coil wire with the terminal areas of a chip unit has been circumvented through use being made, by way of coupling element between the ends of the coil wire pertaining to a wire coil 25 arranged on a coil substrate and the terminal areas of the chip unit, of a contact substrate comprising enlarged terminal areas, so that by virtue of the contact faces of the contact substrate that are very large in comparison with the diameter of the coil wire a contact could be 30 brought about without making great demands as regards the precision of the relative positioning between the ends of the coil wire and the contact faces. Since with the known process the chip unit is equipped with additional contact conductors for the purpose of making contact with the 35 enlarged terminal areas of the substrate, in the case of the manufacturing process known from WO 91/16718 a total of

at least three contacting steps are required in order finally to establish an electrically conductive contact between the terminal areas of the chip unit and the wire coil.

INS.
5 A3>

The object underlying the invention is therefore to propose a process and also a device enabling direct contacting of wire ends on the terminal areas of a chip unit.

10 This object is achieved by means of a process having the features of Claim 1 and by means of a device having the features of Claim 29 or 34.

A INS.
A3> ~~With the process according to the invention, in the course~~
15 of the manufacture of a transponder unit arranged on a substrate and comprising a wire coil and a chip unit, the coil wire is guided in a first process step via the assigned terminal area of the chip unit, or a space that is intended to accept this terminal area, and is fixed to the
20 substrate. By this means an exactly defined alignment of the coil wire relative to the terminal area is obtained after the first process step has been carried out. In the second process step the connection of the wire conductor to the terminal area is then effected by means of a connecting
25 instrument.

By virtue of the process according to the invention there is no longer any necessity, with a view to bringing the terminal areas of the chip unit into contact with the ends
30 of the coil, to provide a separate contact substrate on which enlarged terminal areas are formed. Rather, the coil substrate, which is used in any case as substrate for the wire coil and which, for example in the case where the transponder unit is intended to serve for the manufacture
35 of a chip card, is formed by means of a plastic support sheet corresponding to the dimensions of the chip card, serves virtually as a contacting or positioning aid for the

relative positioning of the ends of the coil in relation to the terminal areas of the chip unit. In this case the chip unit may either be arranged in a recess in the substrate provided for this purpose or may be provided on the surface 5 of the substrate. The first alternative affords the possibility of arranging the chip unit in the recess optionally prior to fixation of the wire conductors or of introducing the chip unit into the recess only after fixation of the wire conductors, in order subsequently to 10 implement the actual contacting of the wire conductors on the terminal areas.

By virtue of the wire conductors which are fixed on the coil substrate the process according to the invention 15 consequently enables simplified contacting of the wire conductors with the terminal areas of the chip unit.

Advantageous embodiments of the process are subjects of Claims 2 and 3.

With one variant of the process, which independently of ~~the~~ process according to Claim 1 for bringing a terminal area into contact with a wire conductor also enables an advantageous arrangement of the wire conductor on the 25 substrate, the wire conductor is subjected to the action of ultrasound in a direction transverse to the wiring plane, and the transverse movement of the wiring device induced by the action of ultrasound is superimposed on the wiring movement extending in the wiring plane.

The superimposition of the wiring movement together with the transverse movement countersinking the cross-section of the wire conductor in the surface of the substrate or bringing it into close contact with the latter enables 35 continuous operation of the wiring device, so that the wire conductor is capable of being connected to the surface of the substrate not only in the region of definite connecting

points but over any length without the actual wiring movement having to be interrupted in the process.

Furthermore, the transverse movement induced by ultrasound proves to be particularly effective during the at least

5 partial countersinking or the close contacting of the cross-section of the wire, since the movement induced by the ultrasound extends in the direction of sinking and not transversely thereto, as is the case with the process described in the introduction.

10

It proves to be particularly advantageous if the transverse movement induced by ultrasound takes place along a

transverse-movement axis that is variable as regards its angle in relation to the axis of the wiring movement. By

15 this means it is possible to adjust the transverse-movement axis so as to conform to the special requirements. Thus it

is possible in the case where an elevated temperature of the wire conductor to be countersunk is desired, possibly depending on the substrate material, to align the

20 transverse-movement axis more in the direction of the wiring-movement axis, in order in this way to obtain a greater longitudinal-force component which acts on the wire conductor and which as a consequence of the associated

rubbing of the wire guide on the wire conductor results in heating of the same. In order to obtain a rate of sinking

25 of the wire conductor in the surface of the substrate that is as high as possible it can be advantageous to align the transverse-movement axis at an angle of 45° to the wiring-movement axis, in order to achieve a shearing effect in the

30 substrate material that is as great as possible.

In order to vary the depth of penetration of the wire conductor into the surface of the substrate, the ultrasonic frequency and/or the angle between the axis of the wiring

35 movement and the transverse-movement axis may also be varied.

With respect to a connecting process following the wiring of the wire conductor in the form of a wire coil on the surface of the substrate for the purpose of connecting the wire conductor to terminal areas of a chip unit it can

5 prove particularly advantageous if the final region of the coil and the initial region of the coil are guided via a recess in the substrate, so that the subsequent connection of the terminal areas of a chip unit to the initial region of the coil and to the final region of the coil can be

10 effected without impairment caused by the substrate material.

In order to enable an alignment of the initial coil region and of the final coil region that is as rectilinear as

15 possible between opposite edges of the recess it is advantageous to interrupt the exposure of the wire conductor to ultrasound in the region of the recess.

An interruption of the exposure of the wire conductor to

20 ultrasound also proves to be advantageous for the purpose of crossing an already wired section of wire in the crossing region, whereby in addition the wire conductor in the crossing region is guided in a crossing plane that is spaced from the wiring plane. This ensures that a crossing

25 of wire conductors becomes possible without it being possible for damage to occur in the process as a result of collision of the wire conductors, which could possibly result in destruction of the insulation of the wire conductors.

30 The use of the process described above in various embodiments has also proved to be particularly advantageous for the manufacture of a card module having a substrate, a coil which is wired on the substrate and a chip unit which

35 is connected to the coil. In this case a coil having an initial coil region and a final coil region is formed on the substrate in a wiring phase by means of the wiring

device, and in a subsequent connection phase a connection to terminal areas of the chip unit is brought about between the initial region of the coil and the final region of the coil by means of a connecting device.

5

As a result of the integration of the wiring of the wire conductor on the substrate into a process for the manufacture of a card module on the basis of any substrate that permits an at least partial penetration of the wire

10 conductor into the surface of the substrate or close contact of the wire conductor against the surface of the substrate, this application of the process enables the

formation of card modules that are easy to handle and that are used as semifinished products in the manufacture of

15 chip cards. With a view to completion of the chip card the card modules are then, as a rule, provided on both sides with laminated surface layers. Depending on the configuration and thickness of the substrate material, the connection between the wire conductor and the substrate

20 material can be effected via a more or less positive inclusion of the cross-section of the wire conductor in the surface of the substrate - for instance, when the substrate is formed from a thermoplastic material - or by means of a predominantly close-contact fixing of the wire conductor on

25 the surface of the substrate, for instance by bonding the wire conductor together with the surface of the substrate.

The latter will be the case, for example, when the substrate material is a fleece-type or woven-fabric-type support.

30

Particularly in the course of the manufacture of paper bands or card bands such as are used, for example, for identifying luggage, the connection of the wire conductor to the surface of the substrate via a layer of adhesive

35 between the wire conductor and the surface of the substrate has proved to be advantageous. In this case the wire conductor comes into close contact against the surface of

the substrate in a peripheral region via the layer of adhesive. If the wire conductor is provided with a suitable surface coating, for example baking lacquer, the layer of adhesive may be formed from the surface coating.

5

With the application of the process as described above, the use of a thermocompression process for connecting the initial region of the coil and the final region of the coil to the terminal areas of the chip unit has proved to be

10 particularly effective.

It is possible for a further increase in the effectiveness of the application of the process as described above to be achieved if a plurality of card modules are manufactured at

15 the same time in such a way that in a feed phase a plurality of substrates arranged collected together in a yield are supplied to a card-module production device comprising a plurality of wiring devices and connecting devices and subsequently in the wiring phase a plurality of 20 coils are formed simultaneously on substrates arranged in a row, then in the connection phase a plurality of chip units are connected via their terminal areas to the coils and finally in a separation phase a separation of the card modules from the composite yield takes place.

25

Furthermore, an application of the process for the manufacture of a rotationally symmetrical coil bobbin has proved advantageous wherein the wire-shaped conductor is wired on a substrate taking the form of a winding support 30 and rotating relative to the wiring device. For the purpose of establishing the relative rotation there is the possibility either to cause the substrate to rotate about its longitudinal axis in the case of a stationary wiring device or, in the case of a stationary substrate, to move 35 the wiring device on a trajectory about the longitudinal axis of the substrate, or even to superimpose the two aforementioned types of motion.

The aforementioned application of the process enters into consideration in particular for the manufacture of a moving coil of a loudspeaker unit that is integrally connected to a vibrating diaphragm.

5

According to another application of the process the process serves to wire a wire-shaped conductor on a substrate by means of a wiring device that subjects the wire conductor to ultrasound with a view to manufacturing a ribbon cable, 10 whereby a number of wiring devices corresponding to the number of cable conductors desired is arranged transversely in relation to the longitudinal axis of a ribbon-shaped substrate and a relative movement between the substrate and the wiring devices takes place in the direction of the 15 longitudinal axis of the substrate.

In order to achieve a reliable and operationally dependable contact between the wire conductor and the terminal areas of the chip unit, which are customarily constituted by 20 aluminium surfaces, it is advantageous, particularly when use is made of a copper wire conductor, to subject the aluminium surface of the terminal areas to a preparatory treatment. With a particularly advantageous embodiment of the process according to the invention the preparatory 25 treatment of the aluminium surface is virtually integrated into the actual connecting operation - that is to say, the contacting of the wire conductor with the terminal areas - by virtue of the wire conductor being connected to the terminal areas by means of a connecting instrument taking 30 the form of an ultrasonic instrument. In this case an oxide layer disposed on the aluminium surface is eliminated mechanically by subjecting the oxide layer to the ultrasonic vibrations of the ultrasonic instrument. This manner of cleansing the aluminium surfaces of the oxide 35 layer, which takes place substantially at the same time as the actual connecting operation, has the particular advantage that with regard to shielding the connecting

points from environmental influences - by creating an inert or reducing atmosphere, for example - it is possible to dispense with special measures intended to prevent the formation of a fresh oxide layer prior to implementation of
5 the connecting operation.

If, on the other hand, as an alternative to the aforementioned ultrasonically induced removal of the oxide layer in conjunction with an ultrasonic connecting operation a
10 preparatory treatment or cleansing process is chosen that is decoupled from the actual connecting operation, the connecting operation itself can be carried out in an inert or reducing atmosphere.

15 The use of etching processes that have great selectivity proves to be particularly advantageous for the purpose of cleansing the aluminium surfaces pertaining to the terminal areas of oxide layers. An example of dry-etching processes is ion-beam etching. But the use of processes that can be
20 implemented easily, such as wet etching or oxide-layer removal by laser treatment, in particular by excimer-laser treatment, is also advantageous.

With a view to preventing renewed oxidation of the
25 aluminium surface there is also the possibility of providing the aluminium surface with a multilayered contact metallisation having a zincate layer applied to the aluminium surface by way of intermediate layer and having an interconnect layer which is disposed on said zincate
30 layer and which is provided for making contact with the wire conductor. In this case the zincate layer serves primarily to eliminate the oxide layer on the aluminium surface, and the interconnect layer, which may for instance consist of nickel or palladium or corresponding alloys,
35 serves to improve the adhesion to the copper wires which are used as a rule by way of wire conductors.

In the case where use is made of an ultrasonic instrument for establishing the connection between the wire conductor and the terminal areas it proves to be particularly advantageous if the vibrational loading of the wire

5 conductor which is brought about by ultrasound takes place in a plane substantially parallel to the terminal area and transverse to, for instance at right angles to, the longitudinal axis of the wire conductor. For, by virtue of the transverse flexibility of the wire conductor which is

10 fixed on the substrate on both sides of the terminal area in the longitudinal direction the greatest possible relative movements can be achieved between the wire conductor and the aluminium surface by means of the ultrasonic loading of the wire conductor which takes place

15 transverse to the longitudinal axis of the wire.

Irrespective of the type and manner of the preparatory treatment and also of the choice of the connecting process it is a particular advantage if by way of coil substrate

20 use is made of a plastic support sheet which together with the coil and the chip unit forms a card inlet for the manufacture of a credit card or such like. Alternatively, differing configurations of the coil carrier are also possible which in each case - that is to say, irrespective

25 of the particular configuration - merely have to enable secure bilateral fixation of the wire conductor relative to the terminal areas of the chip unit. By this means a virtually suspended arrangement and hence a "floating acceptance" of the chip in the substrate also becomes

30 possible. For instance, the use of a sheet of paper by way of coil substrate is also possible, in which connection the wire conductor may be fixed on the substrate via an adhesive layer which is provided on the sheet of paper and which adheres to the wire conductor, or even via an

35 adhesive layer which is provided on the wire conductor itself, for instance a layer of baking lacquer.

Irrespective of the type of coil substrate which is used, it proves to be advantageous if the wire conductor is fixed on the substrate by means of a wiring instrument which is employed in any case for the coil-shaped arrangement of the

5 wire conductor on the substrate and which enables a continuous or intermittent connection of the wire conductor to the surface of the substrate. In this case, particularly when use is made of plastic substrates, it proves to be advantageous if by way of wiring instrument an

10 ultrasonic instrument is employed which enables an at least partial embedding of the cross-section of the wire conductor into the surface of the substrate and hence enables fixation with good adhesion.

15 A particularly good fixation of the wire conductor on the surface of the substrate and the establishment of a particularly reliable connection of the wire conductor to the terminal areas of the chip unit is possible if the ultrasonic instrument which is used for the wiring and

20 fixation of the wire conductor on the substrate brings about a vibrational loading of the wire conductor transverse to the longitudinal axis of the wire conductor and transverse to the surface of the substrate, and if the ultrasonic instrument which is used for connecting the wire

25 conductor to the terminal areas brings about a vibrational loading of the wire conductor in a plane substantially parallel to the substrate and transverse to the longitudinal axis of the wire conductor.

30 The wiring device for wiring a wire-shaped conductor on a substrate by means of ultrasound comprises a wire guide and an ultrasonic generator, whereby the ultrasonic generator is connected to the wire guide in such a way that the wire guide is stimulated to execute ultrasonic vibrations in the

35 direction of the longitudinal axis.

It is advantageous if the device that is suitable for implementing the process according to the invention comprises an ultrasonic instrument with a vibrating punch partially encompassing the cross-section of the wire and having an ultrasonic oscillator which brings about a vibrational loading of the vibrating punch transverse to the longitudinal axis of a wire conductor that is guided by the vibrating punch.

10 According to a preferred embodiment of the device the ultrasonic instrument is coupled to a wire-laying instrument.

A particularly simple configuration of the device becomes possible if the ultrasonic oscillator of the ultrasonic instrument serves simultaneously for ultrasonic loading of the wiring instrument, for instance by the ultrasonic oscillator being arranged in such a way that the axis of its effective direction is variable.

20 According to an alternative solution the wiring device exhibits the features of Claim 34. An advantageous embodiment exhibits the features of Claim 35.

25 It proves to be advantageous for the design of the wiring device if the latter is equipped with a wire-guidance capillary which at least in the region of a wire-guide nozzle extends in the wire guide parallel to the longitudinal axis. In this manner it is ensured that in 30 the region of the wire-guide nozzle the axial advancing movement of the wire conductor is not impaired by ultrasonically induced transverse loads. Rather the ultrasonic loading extends in the longitudinal direction of the wire.

35 For the purpose of introducing the wire conductor into the wire guide, however, it proves to be advantageous if the

wire guide comprises, spaced from the wire-guide nozzle, at least one wire-feed channel extending obliquely in relation to the longitudinal axis of the wire.

5 With a view to avoiding ultrasonically induced transverse loads on the wire conductor in the region of the wire-guide nozzle it also helps if the ultrasonic generator is arranged coaxially with respect to the wire guide.

10 The process according to the invention and devices that are suitable for implementing the process are elucidated below in exemplary manner on the basis of the drawings.

A4>
Fig. 1 shows, in a schematic representation, the wiring of a wire conductor 20 on a substrate 21 by means of a wiring device 22 with a wire guide 23 which is subjected to the action of ultrasound.

The wiring device 22 represented in Fig. 1 is designed to be capable of being displaced along three axes and is subjected to the action of ultrasound which stimulates the wire guide 23 to execute oscillating transverse movements (arrow 24), which in the example represented in Fig. 1 are aligned perpendicular to a wiring plane 28 spanned by lateral edges 25, 26 of a substrate surface 27.

30 For the purpose of wiring, the wire conductor 20 is moved out of a wire-guide nozzle 30 while executing a continuous advancing movement in the direction of the arrow 29,

16

whereby at the same time the wire guide 23 executes a wiring movement 29 which extends parallel to the wiring plane 28 and which in **Fig. 1** can be retraced from the course of the wire-conductor section already wired on the 5 substrate 21. On this wiring movement, which extends in the region of the front lateral edge 25 in the direction of the arrow 29, the oscillating transverse movement 24 is superimposed. This results in an impinging or impacting of the wire-guide nozzle 30 on the wire conductor 20 which is 10 repeated in rapid succession corresponding to the ultrasonic frequency, leading to a compression and/or displacement of the substrate material in the region of a contact point 32.

15 **Fig. 2** shows in a sectional representation, which corresponds roughly to the course of the line of intersection II-II indicated in **Fig. 1**, the embedded arrangement of the wire conductor 20 in the substrate 21. The substrate represented here is a PVC sheet, whereby for 20 the purpose of embedding the wire conductor 20 the wire conductor is subjected via the wiring device 22 to, for example, an ultrasonic power output of 50 W and an ultrasonic frequency of 40 kHz. The contact force with which the wire-guide nozzle 30 is caused to abut the 25 substrate surface 27 may, in the case of the aforementioned substrate material, lie in the range between 100 and 500 N. As is evident from the representation according to **Fig. 2**, in a test which was carried out by adjusting the aforementioned parameters an embedding of the wire 30 conductor 20 into the substrate 21 was obtained substantially by virtue of a compression of the substrate material in a compression region 33 of the substrate material which here is crescent-shaped.

35 The wiring principle represented in **Fig. 1** can be universally employed. For instance, departing from the use elucidated in detail below in connection with the

manufacture of a card module (Figs. 4 to 7), the principle may also find application in connection with the wiring of wire coils in plastic casings, for instance in order to form an aerial for a cordless telephone (mobile phone) or
5 in order to form a measuring coil of a sensor.

Fig. 3 shows the wiring device 22 in an individual representation with an ultrasonic generator 34 which is arranged coaxially with respect to the wire guide 23 and is
10 rigidly connected to the latter in a connecting region 35. Overall the wiring device 22 represented in Fig. 3 is of rotationally symmetrical construction. The wire guide 23 comprises a central longitudinal bore 36 which in the region of the wire-guide nozzle 30 merges with a wire
15 capillary 37 which in comparison with the longitudinal bore 36 has a narrowed diameter that is matched to the diameter of the wire conductor 20. The wire-guidance capillary 37 serves primarily to be able to align the wire conductor exactly in the wiring plane 28 (Fig. 1).

20 In the embodiment example represented in Fig. 3 there are arranged to the side of the wire guide 23, above the wire-guide nozzle and leading into the longitudinal bore 36, two wire-feed channels 38, 39 which extend obliquely downwards
25 in the direction of the wire-guide nozzle 30. The wire-feed channels 38, 39 serve for lateral introduction of the wire conductor 20 into the wire guide 23, so that the wire conductor 20, as represented in Fig. 3, extends laterally on a slant into the wire-feed channel 38, through the
30 longitudinal bore 36 and, guided out of the wire-guidance capillary 37, through the wire guide 23. In this case the multiple arrangement of the wire-feed channels 38, 39 permits selection of the wire-supply side of the wire guide 23 that is most favourable in the given case.

35 As is further evident from Fig. 3, the wire-guide nozzle 30 is of convex construction in the region of a wire outlet 40

in order to enable a deflection of the wire conductor 20 that is as non-damaging as possible in the region of the contact point 32 (**Fig. 1**) or in the region of the wire outlet 40 in the course of the wiring operation represented
5 in **Fig. 1**.

Although not represented in any detail in **Fig. 3**, the wire guide 23 may be equipped with a wire-severing instrument and a wire-advancing instrument. In this case the wire-
10 severing device may be directly integrated into the wire-guide nozzle 30. **Fig. 4** shows a wire conductor 20 which, for the purpose of forming a coil 41 which in this case takes the form of a high-frequency coil, is wired on a substrate 42. The coil 41 here has a substantially
15 rectangular configuration with an initial coil region 43 and a final coil region 44 which are guided away via a window-shaped substrate recess 45. In this case the initial coil region 43 and the final coil region 44 are in parallel alignment with a main coil strand 46 which they accept between them in the region of the substrate recess
20 45. In the course of the ultrasonic wiring of the wire conductor 20 already elucidated in principle with reference to **Fig. 1** the ultrasonic loading of the wire conductor 20 is interrupted while the latter is being guided away via
25 the substrate recess in the course of the wiring operation, in order on the one hand to ensure no impairment of the alignment of the wire conductor 20 in an unrestrained region 47 between the recess edges 48, 49 located opposite one another and on the other hand in order to rule out
30 stressing of the connection between the wire conductor 20 and the substrate 42 in the region of the recess edges 48, 49 by tensile stresses on the wire conductor 20 as a consequence of ultrasonic loading.

35 **Fig. 5** shows, in a configuration that is modified in comparison with **Fig. 4**, a coil 50 with an initial coil region 51 and a final coil region 52 which are guided,

angled in relation to a main coil strand 53, into an interior region of the coil 50. The coil 50 is arranged on a substrate 55 which comprises a substrate recess 56 in the interior region 53 of the coil 50. In order to be able to 5 guide away both the initial coil region 51 and the final coil region 52 via the substrate recess 56, in the case of the configuration represented in **Fig. 5** the final coil region 52 has to be guided away beforehand in a crossing region 57 via the main coil strand 44. In order in this 10 case to prevent damage to or a partial stripping of the wire conductor 20, similarly as in the region of the substrate recess 56 the ultrasonic loading of the wire conductor 20 is interrupted in the crossing region 57. Furthermore, the wire guide 23 is slightly raised in the 15 crossing region 57.

Fig. 6 shows, in a view of the substrate 55 corresponding to the course of the line of intersection VI-VI in **Fig. 5**, the placement of a chip unit 58 in the substrate recess 56, 20 wherein terminal areas 59 of the chip unit 58 are caused to abut the initial coil region 51 and the final coil region 52.

Fig. 7 shows the subsequent connection of the terminal 25 areas 59 of the chip unit 58 to the initial coil region 51 and to the final coil region 52 by means of a thermode 60 which under the influence of pressure and temperature creates a connection by material closure between the wire conductor 20 and the terminal areas 59, as an overall 30 result of which a card module 64 is formed.

In the case of the chip unit 58 represented in **Figs. 6** and 35 **7** it may also be a question, as in all other remaining cases where mention is made of a chip unit, either of an individual chip or of a chip module which, for instance, comprises a chip which is contacted on a chip substrate or even a plurality of chips. Furthermore, the connection

represented in **Figs.** 6 and 7 between the coil 50 and the terminal areas 59 is not restricted to the connection to one chip but applies generally to the connection of electronic components comprising terminal areas 59 to the 5 coil 50. In this case it may be also a question, for example, of capacitors.

Furthermore, it becomes clear from **Figs.** 6 and 7 that the substrate recess 56 is so dimensioned that it substantially 10 accepts the chip unit 58. With a view to simplifying the alignment of the terminal areas 59 of the chip unit 58 in the course of the placement of the chip unit 58 preceding the actual contacting, the chip unit 58 may be equipped on its contact side 61 comprising the terminal areas 59 with 15 an alignment aid 62 which here is constructed in the manner of a bridge. The alignment aid 62 is dimensioned so as to correspond to the spacing a which the initial coil region 51 and the final coil region 52 have from one another in the region of the substrate recess 56 (**Fig.** 5).

20 **Fig.** 8 shows a production device 63 that serves for the manufacture of card modules 64 that are used as semi-finished products in the manufacture of chip cards. The card modules 64 manufactured by means of the production 25 device 63 here have, by way of example, the structure represented in **Figs.** 5, 6 and 7 with, in each instance, a coil 50 and a chip unit 58 arranged on a common substrate 55.

30 The production device 63 represented in **Fig.** 8 comprises five stations, namely a feed station 65, a wiring station 66, an assembly station 67 and a connection station 68 as well as an extraction station 69.

35 In the feed station there is supplied to the production device 63 a so-called yield 70 which exhibits in a common composite a plurality of substrates 55 - here for

representational reasons only twenty - which are connected to one another via points of separation which are not represented here in any detail. The yield 70 is supplied by means of a transport instrument 71 to the wiring station

5 66 which comprises at a portal 73, which extends transversely in relation to the production direction 72 and is capable of being displaced in the production direction 72, four identical wiring devices 22 arranged in a row. The wiring devices 22 are supplied with the wire conductor
10 20 via four wire-conductor coils 74. For the purpose of forming the coil configurations represented by way of example in **Fig. 5**, the wiring devices 22, which are capable of being displaced along the portal 73, are displaced appropriately in the wiring plane 28, (**Fig. 1**).
15

After wiring of the wire conductors 20 corresponding to the coil configuration represented in **Fig. 5**, the yield 70 with the coils 50 formed thereon is moved on further to the assembly station 67. In the present case the connection
20 station 68 is combined with the assembly station 67 in such a way that, on a portal 75 which is capable of being displaced in the production direction 72, both an assembly device 76 and a connecting device 77 are arranged so as to be capable in each instance of being displaced in the
25 longitudinal direction of the portal 75. In this case the assembly device 76 serves for extraction of chip units 58 from a chip-unit reservoir 78 and for subsequent placement of the chip units 58 in the manner represented in **Fig. 6**. The connecting device 77 serves to bring the terminal areas
30 59 of the chip units 58 into contact with the coil 50, as represented in **Fig. 7**.

After assembly and contacting, the yield 70 is moved on further into the extraction station 69. Here an extraction
35 of the yield 70 takes place with subsequent separation of the substrates 55, or firstly a separation of the substrates 55 - that is to say, a dispersion of the

composite yield - and subsequently the extraction of the individual substrates 55 which now take the form of card modules 64.

5 **Fig. 9** shows a particular application of the process elucidated by way of example on the basis of **Fig. 1** for the manufacture of a cylindrical formed coil 79 wherein the substrate takes the form of a cylindrical winding support 80 and the wiring or embedding of the wire conductor 20 on the winding support 80 is effected in the course of rotation 81 of the winding support 80 with simultaneous superimposed translation 82 of the wiring device 22.

10 As **Fig. 10** shows, the winding support 80 may also take the form of a cylindrical extension of a plastic vibrating diaphragm 83 of a loudspeaker unit 84, so that in the manner represented in **Fig. 9** a moving coil 85 is capable of being manufactured such as serves, in combination with a permanent magnet indicated in **Fig. 10**, to form a 15 loudspeaker unit 84.

20 **Fig. 11** shows, by way of another possible application of the process that has been described, a ribbon-cable section 85 with a substrate 86 taking the form of a ribbon cable which, adjoined on both sides by points of separation 87, is provided with substrate recesses 88 arranged in a row transverse to the longitudinal direction of the substrate 86. On the substrate 86 there are located, arranged parallel to one another and extending in the longitudinal 25 direction of the substrate 86, a plurality of wire conductors 20 which are wired on the substrate 86 in the manner represented by way of example in **Fig. 1**. In this case the wire conductors 20 are guided away in the region of the points of separation 87 via the substrate recesses 30 88. The points of separation serve for the definition of predetermined ribbon-cable pieces 89, whereby the substrate recesses 88 are then arranged in each instance at one end 35

of a piece of ribbon cable. In particularly favourable manner this results in contacting possibilities for connector plugs or connector sockets with the wire conductors 20 without the wire conductors having firstly to
5 be exposed for this purpose. The substrate recesses 88 are introduced into the substrate 86 in a stamping process with an appropriately formed punch tool, whereby as a result of the spacing of the stampings the spacing of the points of separation 87 is preset. Subsequently the appropriately
10 prepared continuous substrate is covered with the wire conductors 20, whereby in this case a number of wiring devices corresponding to the number of wire conductors 20 are arranged above the substrate which is moved longitudinally.

15 **Fig. 12** shows, in a modification of the wiring device 22 represented in **Fig. 3**, a wiring device 91 which, like the wiring device 22, comprises an ultrasonic generator 34. As distinct from the wiring device 22, there is no wire guide fastened to the connection region 35 of the ultrasonic generator 34 but rather a vibrating punch 92 which, as represented in **Fig. 12**, serves to subject the wire conductor 20 which is guided between a profiled end 93 and the surface of the substrate 21 to the action of mechanical vibrations extending in the longitudinal direction of the vibrating punch 92 and induced by ultrasound. In order in this case to enable reliable guidance of the wire conductor 20, the profiled end 93 is provided with a concave recess which is not represented in **Fig. 12** in any detail and which
25 enables partial encompassing of the wire conductor 20.
30

As distinct from the wiring device 22 represented in **Fig. 3**, on the wiring device 91 a wire guide 94 is provided which, in the case of the embodiment example represented
35 here, is formed from a guidance tube 95 arranged laterally on the ultrasonic generator 34 with an elbow nozzle 96 which is formed in the direction of the profiled end 93 and

which enables lateral supply, here directed obliquely downwards, of the wire conductor 20 in the direction of the profiled end 93. Hence, as represented in Fig. 12, the wire conductor 20 can be guided between the profiled end 93 of the vibrating punch 92 and the surface of the substrate 21 in order to enable the previously described connection to, or alternatively wiring on, or in, the surface of the substrate 21.

10 Departing from the representation in Fig. 12, it is also possible to provide the wire guide on the wiring device 91, decoupled from the ultrasonic generator 34, in order where necessary to enable vibration-free supply of the wire conductor.

15 In the case of the embodiment example represented in Fig. 12 the wiring device comprises a wire coil 99 which is capable of rotating about a winding axis 98 arranged transverse to the punch axis 97 and which serves to supply 20 the wire conductor 20 into the wire guide 95.

In order to enable arbitrary wiring of the wire conductor 20 on the surface of the substrate 21, the wiring device 91 comprises, coaxially with respect to the punch axis 97, a 25 pivotal axis 100.

In the language of the present patent application the terms "wire-shaped conductor" and "wire conductor" generally designate conductors for the transmission of signals that 30 have a defined longitudinal extent and therefore with respect to their external shape are of wire-shaped construction. However, the term "wire conductor" is not restricted to metallic conductors but also designates conductors made of other materials, for example light 35 guides made of glass fibre, or even conductors that serve for the guidance of flowing media. Particularly in the case where the conductors used are provided with an

adhesive surface it is also possible for the conductors to be disposed in multiple layers located on top of one another, the lowest layer being connected to the surface of the substrate and other layers being connected in each instance to conductor layers arranged below them. The adhesion may, for example, be obtained via a coating of the conductor with baking lacquer which with regard to its adhesive effect is capable of being activated by means of the action of heat, or via an appropriate plastic coating.

20 **Fig. 15** another sectional representation of the card inlet represented in **Fig. 13** according to the course of the line of intersection III-III;

25 **Fig. 16** a representation corresponding in its view to **Fig. 14** for the purpose of elucidating an alternative procedure with subsequent application of a chip unit;

30 **Fig. 17** the contacting of the chip unit applied subsequently according to **Fig. 17**;

35 **Fig. 18** a possible contact metallisation of a terminal area of a chip with contacting according to the process represented in **Fig. 17**;

Fig. 19 another possible contact metallisation of a terminal area of a chip;

Fig. 20 a representation corresponding in its view to **Fig. 14** of a transponder unit arranged on a coil substrate.

Fig. 13 shows a chip-card inlet 110 which, with a view to
5 the manufacture of a chip card by way of end product which
is not represented in any detail here, is provided with
bilateral surface layers which as a rule are applied onto
the chip-card inlet in the form of laminated layers
covering the surface.

10

The chip-card inlet 110 consists here of a coil substrate
111 formed from plastic material, onto which a wire coil
112 is applied with the aid of wire-laying technology. To
this end a wire conductor 113 is wired on the surface of
15 the coil substrate 111 by means of a wiring instrument
which is not represented in any detail in **Fig. 13** and is
partially embedded into the coil substrate 111 by
ultrasonic loading, as can be gathered from **Fig. 14**.

20 As is evident furthermore from the representation according
to **Fig. 13**, in the coil substrate 111 a recess 114 is
provided which serves to accept a chip unit constituted
here by an individual chip 115. The chip unit may, as in
the present case, be constituted merely by the chip 115.
25 However, it is further possible for the chip unit to be
formed from a so-called "chip module" which accepts one or
even several cased chips.

As is further evident from **Fig. 13**, the wire conductor 113
30 which is wired for the purpose of forming the wire coil 112
on the coil substrate 111 is contacted with wire ends 116,
117 on an assigned terminal area 118 and 119, respectively,
of the chip 115.

35 A process for implementing the contacting of the wire ends
116, 117 with the terminal areas 118, 119 of the chip 115
will be elucidated in more detail below with reference to

Fig. 14. The process represented in detail in **Fig. 14** is effected in two successive phases, which here for the purpose of differentiation are denoted by I and II. In the phase designated by I the wire end 116 illustrated here is 5 fixed on the coil substrate 111, whereby simultaneously as a consequence of the aforementioned wiring process for applying the wire conductor 113 onto the surface of the coil substrate 111 the wire conductor 113 is guided away via the chip 115 that is received in the recess 114. With 10 a view to implementing the process represented in **Fig. 14**, the coil substrate 111 is arranged on a table 120 together with the chip 115 received in the recess 114.

By way of wiring instrument, in the case of the process 15 example represented in **Fig. 14** use is made of an ultrasonic instrument 121 which with a vibrating punch 122 embeds the wire conductor 113 which is continuously guided out of a wire guide 123 into the surface of the coil substrate 111 and thereby simultaneously executes a horizontal movement 20 124 on the surface of the coil substrate 111. This application of the wire conductor 113 on the surface of the coil substrate 111, which is described by the term "wiring", is firstly effected in the region designated by Ia to the left of the recess 114, subsequently the wire 25 conductor 113 is guided away with the wire guide 123 via the chip 115 which is arranged in the recess 114, in order finally to continue with the fixation of the wire conductor 113 on the right-hand side of the recess 114 in the region headed by Ib by means of ultrasonic loading of the wire 30 conductor via the vibrating punch 122. Although when use is made of the ultrasonic instrument 121 described above for wiring the wire conductor 113 on the coil substrate 111 a fixation of said wire conductor arises extending substantially over the entire length of the wire conductor 35 113 on the coil substrate 111, in order to realise the principle of the process it is sufficient if a fixation of the wire conductor 113 on the coil substrate 111 is

effected merely at two points to the left and right of the recess 114, in order to achieve the linear alignment of the wire conductor 113 represented in **Fig. 14** via the terminal areas 118, 119 of the chip 115.

5

After the wire conductor 113 is located in the position spanning the assigned terminal area 118 of the chip 115, in the phase denoted by II the connection of the wire conductor 113 to the terminal area 118 is effected. To this end use is made, in the process example represented in **Fig. 14**, of another ultrasonic instrument 125 which, as is evident in particular from **Fig. 15**, comprises a profiled end 126 pertaining to a vibrating punch 127 and provided with a concave recess.

10

The process described above with reference to **Figs. 14** and **15** also offers the possibility, by appropriate choice of the points of fixation of the wire conductor on the substrate, of guiding the wire conductor away diagonally via the terminal areas, in order to increase the overlap between the wire conductor and the terminal areas. Also, several chips or other elements arranged in series on, or in, a substrate can be connected by means of the wire conductor in the manner represented in **Fig. 14**.

15

Furthermore, **Fig. 15** shows clearly that, in contrast with the vibrational loading 128 induced by ultrasound which is effected in the longitudinal direction of the vibrating punch 122 of the ultrasonic instrument 121, the vibrational loading 129 of the vibrating punch 127 induced by ultrasound is effected transverse to the longitudinal direction of the wire conductor 113 and parallel to the surface of the coil substrate 111. On this vibrational loading 128 a slight contact pressure 130 is superimposed, so that the wire conductor 113 which is received in guided manner in the profiled end 126 of the vibrating punch 127 is moved back and forth in oscillating manner under

pressure in the region of the terminal area 118 above the latter. On the one hand this results in any oxide skins that may be present on the terminal area 118 being ripped open and eroded, on the other hand a welding subsequently 5 results, given appropriately high or increased contact pressure 130, of the wire conductor 113, which here is formed from copper, to the aluminium terminal area 118. In case the wire conductor 113 is provided with an external insulation the latter can also be removed by the 10 oscillating movement back and forth in the region of the terminal area 118, so that subsequently the metallic connection previously described between the wire conductor, which immediately beforehand is still protected against 15 oxidation by the insulation, and the terminal area becomes possible.

In the coil substrate 111 represented in Figs. 14 and 15 the recess 114 is arranged so as to be larger than the corresponding dimensions of the chip 115, so that a 20 circumferential gap 130 results between the chip 115 and the edges of the recess 114. By this means a virtually "floating acceptance" of the chip 115 in the recess 114 is possible, whereby, although said chip is substantially defined in its location relative to the coil substrate 111, 25 it is able to execute minor relative movements. This results in the advantage that, by virtue of the laminating operation described in the introduction for application of the bilateral surface layers onto the coil substrate 111, the chip can at least partially avoid the pressure loads 30 associated with the laminating operation and consequently the risk of damage to the chip in the course of the laminating operation is significantly reduced.

In order also in the case of the "floating acceptance" of 35 the chip in the recess 114 described above to be able to carry out an exact positioning of the wire conductor 113 on the terminal area 118, the wire conductor 113 can be

tracked via a corresponding transverse-movement axis 131 of the ultrasonic instrument 125.

Although with reference to the process example represented in Figs. 14 and 15 two different ultrasonic instruments 121 and 125 were mentioned in the foregoing description, there is also the possibility, given appropriate design of the ultrasonic instrument 121, of making use of the latter both for the wiring and/or fixation of the wire conductor on the surface of the coil substrate 111 and for the connection of the wire conductor 113 to the respectively assigned terminal area 118 or 119.

A way of proceeding that is slightly varied in comparison with Figs. 14 and 15 is represented in Figs. 16 and 17, wherein only after fixation of the wire conductor 113 on the surface of the coil substrate 111 on both sides of the recess 114 is a chip 132 introduced into said recess. In order simultaneously with the introduction of the chip 132 into the recess 114 to enable a positioning that is suitable for the subsequent contacting of the wire conductor 113 with an assigned terminal area 133 of the chip 132, the latter is equipped on its contact side 134 with bridge-type alignment aids 135, in each instance arranged adjacent to a terminal area 133, which provide for correct relative positioning via guide bevels 136.

Fig. 17 shows, in addition, a thermode instrument 137 which can be employed as an alternative to the ultrasonic instrument 125 by way of a connecting instrument which enables a connection of the wire conductor under pressure and temperature loading to the assigned terminal area 133. With both of the connection processes represented in Figs. 14, 15 and 17 there is, in principle, the possibility of establishing the connection between the wire conductor and the terminal areas by a superimposition of ultrasonic

loading and temperature loading, for example by means of a heatable ultrasonic instrument.

In order to enable a connection of the copper wire conductor 113 to the aluminium terminal areas 133 of the chip 132, the terminal areas 133 are provided with a contact metallisation 138 (Fig. 18) or 139 (Fig. 19). The contact metallisations 138, 139 comprise, in corresponding manner, a zincate layer serving as intermediate layer 140 which serves as foundation for a nickel layer 141 applied to it in the case of the contact metallisation 138, or a palladium layer 142 in the case of the contact metallisation 139. With a view to improving the connecting capacity or with a view to increasing the oxidation resistance, the nickel layer 141 is also provided with a gold coating 145. For the purpose of clarifying the size dimensions, layer thicknesses of the layers that are applied to the aluminium coating, about 1 to 2 μm in thickness, of the terminal area 133 are given below by way of examples:

zincate layer:	$d = 150 \text{ nm};$
nickel layer:	$d = 1 - 5 \mu\text{m};$
palladium layer:	$d = 1 - 5 \mu\text{m};$
gold coating:	$d = 100 - 150 \text{ nm}.$

T0310
25

Fig. 20 finally shows, in a variant of the representation according to **Fig. 13**, the possibility of applying the process described above also for the direct contacting of the wire conductor 113 with assigned terminal areas 118 and 119 of the chip 115 if the chip 115 is not arranged in a recess but rather on the surface of a substrate 143. In the case of the substrate 143 represented in **Fig. 20** it may be a question, for example, of a paper substrate or of any other substrate. Conforming with the process elucidated with reference to **Figs. 14** and **15**, here too on both sides of an acceptance region or arrangement region 144 for the

chip 115 a fixation is provided of the wire conductor 113 into the surface regions of the substrate 143, here designated in simplified manner by Ia and Ib.

5 In particular on account of the particularly thinly formed substrate the embodiment represented in Fig. 20 appears to be particularly suitable for use as a transponder arrangement in connection with the identification of luggage. Although in the foregoing embodiment examples
10 reference is made, with a view to elucidating the process, to transponder units consisting of a coreless wire coil and a chip unit, use may of course also be made of ferrite-core coils such as are employed, for example, for the manufacture of animal transponders.

15 In any case, the chip or the chip unit can be made thinner prior to or after the application on, or in, the substrate, in order to increase the flexibility of the chip and, where appropriate, to adapt the chip to the substrate as regards
20 its bending behaviour.
